Abstract

3D Structural modeling is a major instrument in geosciences, e.g. for the assessment of groundwater and energy resources or nuclear waste underground storage. Fault network modeling is a particularly crucial step during this task, for faults compartmentalize rock units and play a key role in subsurface flow, whether faults are sealing barriers or drains.

Whereas most structural uncertainty modeling techniques only allow for geometrical changes and keep the topology fixed, we propose a new method for creating realistic stochastic fault networks with different topologies. The idea is to combine an implicit representation of geological surfaces which provides new perspectives for handling topological changes with a stochastic binary tree to represent the spatial regions. Each node of the tree is a fault, separating the space in two fault blocks. Changes in this binary tree modify the fault relations and therefore the topology of the model.

Résumé

Simulations stochastiques de réseaux de failles en modélisation structurale 3D. La modélisation structurale est largement utilisée en géoscience, notamment pour l'évaluation des ressources énergétiques et hydriques du sous-sol. La caractérisation des failles est l'une des étapes clés du processus de modélisation étant donné leur importance dans les écoulements de subsurface.

Alors que la plupart des techniques de modélisation d'incertitudes structurales existantes perturbent seulement la géométrie des objets, nous proposons une nouvelle méthode de simulation stochastique de réseaux de failles, incluant des changements topologiques. Cette méthode associe une modélisation implicite des surfaces géologiques, avec un arbre binaire permettant d'agencer les régions spatiales du modèle. Chaque noeud de l'arbre représente une faille, séparant l'espace en deux blocs. Des changements dans l'arbre binaire modifient les relations entre failles et par conséquent la topologie du modèle.

1. Introduction

A 3D structural model of the subsurface helps visualizing, understanding and quantifying geophysical processes and assessing natural resources. Indeed, geological structures control to some extent the spatial layout of subsurface heterogeneities. Therefore, most geostatistical petrophysical modeling methods use distances which follow folded and faulted structures [1–3]. Moreover, physical modeling codes are best run on grids conforming to geological structures [4–6].

However, surface geology and borehole data only provide limited information about subsurface structures and even exhaustively sampled 3D seismic surveys cannot remove interpretational uncertainties. Uncertainties are due to the inherent incompleteness and the limited resolution of geological data sets. Geology is by nature an interpretive science [7] and geological concepts and physical laws help geoscientists reducing uncertainties. However, geoscientists may introduce a prior geological knowledge bias and/or human bias [8] when interpreting subsurface data.

These uncertainties have a wide range of consequences in quantitative geosciences, and Gilbert [9] and Chamberlin [10] in their pioneering work already argued for multiple hypotheses. Consequently, uncertainties can be assessed by considering not just one (probably wrong) deterministic model, but a set of possible structural models. Depending on the amount and quality of observations, three levels of uncertainty can be defined by comparing such possible 3D structural models:

- Low uncertainty when all models have the same layout of structural surfaces, and show relatively small geometric variations.
- Medium uncertainty when the geometry of surfaces changes more significantly and the connection between geological surfaces may vary locally.
- High uncertainty when the number of structural interfaces, their spatial layout and their geometry are globally variable, except at some observation points.

From a modeling standpoint, these three degrees of uncertainty correspond to increasing difficulty. Therefore, multi-realization methods have mostly focused on low and medium uncertainty, primarily to assess risk in hydrocarbon reservoir management (rock volume estimates [11], underground flow [12], well planning [13], history matching [14]). Most of these methods proceed by perturbing a reference interpretation to generate a large number of equiprobable geometric models of geological structures. In faulted formations, this may tend to underestimate variability by perturbing only fault geometry and leaving the first-order fault connectivity constant. Therefore, existing methods are best suited for large scale studies (pluri-decamic) with high-resolution 3D seismic data. For smaller objects or sparser data, stochastic approaches

should also sample large uncertainties when generating possible models, some of which should be falsified whenever a new observation is made [15].

In this paper, we propose to sample both the connectivity and the geometry of fault networks in order to account for large uncertainties due to limited data quantity and resolution. Faults indeed are key elements in 3D structural models, and often have a first-order impact on the modeling output.

After a review of uncertainty modeling methods using both traditional explicit modeling or recent implicit approach (section 2), we introduce our stochastic fault simulation method (section 3).

2. Structural uncertainties: state of the art

Most existing structural uncertainty modeling methods proceed by perturbing a reference interpretation. The result is a large number of equiprobable geometries representing the uncertainty relative to geological structures.

2.1. Explicit geometrical perturbation techniques and limitations

Figure 1: Topology changes induced by geometrical changes. In the reference case, the horizon H is in between faults F_1 and F_2 . A simple drift of H along uncertainty vectors may completely change the configuration: H could possibly occur on either side of F_1 or F_2 and not anymore in between the two faults.

Fig. 1. Changements topologiques induits par des perturbations géométriques. Dans le cas initial, l'horizon H se situe entre les failles F_1 et F_2 . Une simple translation de H le long de vecteurs d'incertitude peut complètement changer la configuration : H pourrait être en contact avec seulement F_1 ou F_2 et ne plus se situer entre les deux failles.

In explicit modeling, geological interfaces are represented as polygonal surfaces. Lecour *et al.* [16] propose to modify the geometry of a surface by perturbing its nodes along an uncertainty bar defined at each node. The perturbation is correlated along the

surface using the probability field method [17], in order to obtain realistic geometries. In the case of fault perturbation, curvature sign along the sliding direction is preserved to ensure fault compliance.

Other techniques have been developed to perturb the geometry of structural models, keeping the topology fixed [14, 18–20]. For a whole model, each surface is perturbed according to its structural uncertainties and all connections (horizon to horizon, horizon to fault and fault to fault) are stored. Once all geological objects have been perturbed, connections are honored so that the topology is preserved [16]. In practice, this raises a number of challenges to maintain model consistency in the case of large uncertainties, for interferences between surfaces and large mesh distortions may occur. Moreover, large geometrical uncertainties may require topology changes, for instance horizon to fault connections (Fig. 1).

2.2. Topological perturbation

Topology is all about connections and relations between objects. In a structural model, topological changes may be introduced in different manners:

- Adding or removing geological objects.
- In the case of faults, changing the truncation rule between two faults.
- During geometrical perturbations, a simple drift of an horizon along uncertainty vectors may induce a topological change (especially fault to horizon connections, Fig. 1).

Few methods have been proposed to change the topology of a structural model. A fault modeling tool, referred to as Havana has been proposed in [21, 22]. It is mainly designed for the oil industry and works directly on a corner-point reservoir grid used for flow simulations. This choice allows for directly observing the effects of structural uncertainties on flow simulations. However, reservoir grids have known shortcomings to accurately represent geological structures. Consequently, sub-seismic faults are added by simply modifying the permeability field. Main faults are bilinear planes parallel to the pillars of the reservoir grid or stair-stepped faults.

In our approach, we borrow the idea of fault operator to [21], but use a flexible representation of faults. This makes it possible to account for large structural uncertainties without making simplifications due to the grid orientation. For accuracy, this method uses an implicit representation of structural interfaces, as in [23–25].

2.3. Implicit modeling: new perspectives for 3D modeling

An implicit surface (e.g. Fig. 3d) is described by an isovalue f of a monotonic volumetric function $\mathcal{F}(x, y, z)$ (e.g. Fig. 3a,c) (e.g. the geological time [26], the signed distance to an object [27]):

$$\mathcal{F}(x, y, z) = f \quad (1)$$

A conforming stratigraphic column is then represented as a set of isopotentials of a same scalar field, whereas unconformities and faults are defined by their own scalar

Figure 2: Boolean operations in implicit modeling. *a.* Left: two surfaces A ($\mathcal{F}_A(x, y, z) = f_A$) and B ($\mathcal{F}_B(x, y, z) = f_B$) and their corresponding half-spaces. Right: boolean sum of the two scalar fields defining four spatial regions. *b.* Example of boolean operation: $\mathcal{F}_A(x, y, z) \cap \mathcal{F}_B(x, y, z) \geq f_B$. *c.* Example of truncation corresponding to the operation: $\mathcal{F}_A(x, y, z) = f_A \cap \mathcal{F}_B(x, y, z) \geq f_B$ (equation 2).

Fig 2. Opérations booléennes en modélisation implicite. *a.* Gauche : deux surfaces A ($\mathcal{F}_A(x, y, z) = f_A$) et B ($\mathcal{F}_B(x, y, z) = f_B$) et leurs demi-espaces. Droite : 4 régions spatiales définies par l'intersection des deux champs scalaires. *b.* Exemple d'opération booléenne : $\mathcal{F}_A(x, y, z) \cap \mathcal{F}_B(x, y, z) \geq f_B$. *c.* Exemple d'intersection : $\mathcal{F}_A(x, y, z) = f_A \cap \mathcal{F}_B(x, y, z) \geq f_B$ (équation 2).

field. Consequently, horizons can be perturbed independently of faults. Truncations by faults are only honored when an explicit surface is extracted from an isovalue of a scalar field.

Implicit modeling provides a means to easily truncate some surfaces by others using Constructive Solid Geometry (CSG) concepts. For instance, a surface A ($\mathcal{F}_A(x, y, z) = f_A$) can be truncated by another implicit surface B ($\mathcal{F}_B(x, y, z) = f_B$), by making a boolean intersection between A and either half-spaces of B (Fig. 2). For instance, a truncated surface $A|_{B^+}$ is defined by:

$$\mathcal{F}_A(x, y, z) = f_A | \mathcal{F}_B(x, y, z) \geq f_B \quad (2)$$

The reference scalar field of an implicit surface ($\mathcal{F}(x, y, z) = f$) can be perturbed by introducing a correlated random field $\mathcal{R}(x, y, z)$ [18]. The new surface is defined by the same isovalue f in the field $\mathcal{F}(x, y, z) + \mathcal{R}(x, y, z)$ (Fig. 3).

3. A new method for stochastic simulations of fault networks

The proposed stochastic fault simulation method takes advantage of the implicit surface perturbation and CSG operations between faults. To represent how faults partition the domain and interact one with another, we propose using a binary tree.

Figure 3: Geometrical perturbation method in implicit modeling. *a.* The reference scalar field $\mathcal{F}(x, y, z)$ defining the initial implicit surface (isovalue f , planar surface). *b.* A correlated random field $\mathcal{R}(x, y, z)$ generated by Sequential Gaussian Simulation represents the perturbation field. *c.* The surface is now defined by the isovalue f in the field $\mathcal{F}(x, y, z) + \mathcal{R}(x, y, z)$. *d.* View of the perturbed surface.

Fig 3. Méthode de perturbation géométrique en modélisation implicite. *a.* Le champ scalaire de référence $\mathcal{F}(x, y, z)$ définit la surface initiale (isovaleur f , surface plane). *b.* Un champ aléatoire corrélé généré par une Simulation Séquentielle Gaussienne correspond au champ de perturbation. *c.* La surface est maintenant définie par l'isovaleur f dans le champ $\mathcal{F}(x, y, z) + \mathcal{R}(x, y, z)$. *d.* Surface perturbée.

3.1. Binary trees as descriptors of fault relationships

Indeed, each fault divides the model \mathcal{M} in two distinct fault blocks B^- and B^+ [28], defined by:

- $B^- = \{(x, y, z) \in \mathcal{M} | \mathcal{F}(x, y, z) < f\}$
- $B^+ = \{(x, y, z) \in \mathcal{M} | \mathcal{F}(x, y, z) > f\}$

Then, in the binary tree representing a fault network, each node represents a fault and each leaf (node without children) represents a fault block (Fig. 4).

Each fault in the tree is potentially a branching fault for its parent faults in the tree. Switching a parent and its child in the tree changes their relationship: the main fault becomes the branching fault and inversely (Fig. 5). A special case may occur when a

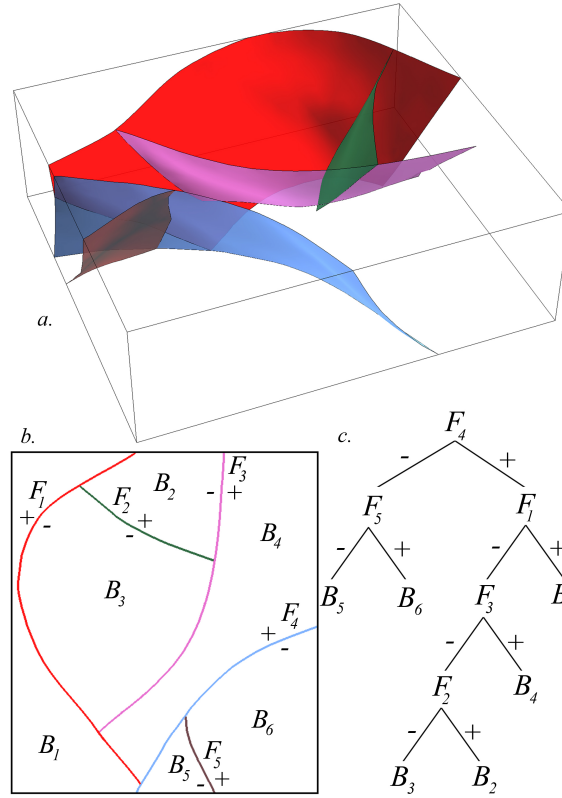

Figure 4: A fault network and its topological representation as a binary tree. *a.* Fault network in 3D. *b.* The same model in top view to make the topology more explicit. Each fault F_i divides the model in two blocks B_i . *c.* Binary tree representing the fault relationships. The fault F_4 is the main and oldest fault (root node of the tree), other faults are branching faults.

Fig. 4. Un réseau de failles et sa représentation topologique en arbre binaire. *a.* Réseau de failles en 3D. *b.* Le même modèle vu de dessus afin d'expliciter la topologie. Chaque faille F_i coupe le modèle en deux blocs B_i . *c.* Arbre binaire représentant les relations entre failles. La faille F_4 est la faille principale (racine de l'arbre), les autres failles étant des failles secondaires.

fault F cuts a set of older faults $S_{old} = \{F_i | i \in [1, n]\}$. In this case, the oldest faults S_{old} are on both sides of the cutting fault F in the 3D model, hence they appear in the two branches of F in the tree (Fig. 5c).

When modeling a given fault array, some faults may not be truncated by other faults. Therefore, individual faults can be considered either parent or child in the binary tree, there is no consequence in term of truncation since faults are not in contact. Consequently, a given fault network may be described by several binary trees (Fig. 6). As there is no one-to-one correspondence between a fault network and a binary tree, the latter should be considered as a hierarchy of fault events, the oldest fault being the root of the tree, except for faults offset by more recent faults. Nevertheless, a tree fully defines the topology of the fault network.

Figure 5: Consequences of filiation relationships in a binary tree from a geological point of view. *a.* The fault F_1 is the root, F_2 is a branching fault. *b.* Inversion of the relationship. F_1 is now a branching fault. *c.* A fault F_2 being on both sides of F_1 means that F_2 is cut by F_1 . F_2 is the child of F_1 in the tree although it is the oldest fault.

Fig. 5. Conséquences des relations de filiation dans un arbre binaire d'un point de vue géologique. *a.* La faille F_1 est la racine de l'arbre, F_2 est la faille secondaire. *b.* Inversion de la relation père-fils. F_1 est maintenant la faille secondaire. *c.* Une faille F_2 présente des deux côtés de F_1 signifie que F_2 est recoupée par F_1 . F_2 est la fille de F_1 dans l'arbre bien qu'elle soit plus ancienne.

3.2. Fault array simulations

3.2.1. Fault network composition

We consider a fault network composed of one or several fault families. Fault families regroup faults having similar structural parameters (orientation, type). If only a few data about a fault family is available, it can be described by statistical input parameters:

- a relative age
- a number of faults
- orientation (dip and strike) distributions
- perturbation parameters

Alternatively, fault families may be described by any scalar field (e.g. coming from the interpolation of field, borehole or seismic data) and perturbation parameters defining the associated uncertainties. The key input parameter is the relative age of faults since it determines the order of simulation and thus the place in the binary tree (section 3.2.3).

To simulate a fault array, only one binary tree is needed, containing all the faults of the network. Different fault networks are obtained by generating different binary trees.

3.2.2. Method for simulating a fault

For a given fault family, each fault is simulated as follows:

- Add a leaf randomly in the tree (i.e. choose randomly a fault block).
- Define the initial fault surface by a reference field $\mathcal{F}(x, y, z)$ from statistical parameters or input scalar field.
- Perturb the initial geometry by simulating a noise $\mathcal{R}(x, y, z)$ using a Sequential Gaussian Simulation, set to 0 perturbation at data location (method presented in Fig. 3).
- Define the fault by the field $\mathcal{F}'(x, y, z) = \mathcal{F}(x, y, z) + \mathcal{R}(x, y, z)$.
- Draw an isovalue f from the range of values that occurs in the selected block to define the fault by $\mathcal{F}'(x, y, z) = f$.

For a model \mathcal{M} containing n fault blocks $B_{i|i \in [1, n]}$, let be p_i the probability for the block B_i to be selected for containing the new fault, with $\sum_{i=1}^n p_i = 1$. Different strategies are possible to define $p_{i|i \in [1, n]}$. For instance, a uniform probability law can be used:

$$p_{i|i \in [1, n]} = \frac{1}{n} \quad (3)$$

Using this strategy, no block is privileged and fault blocks totally different in volume may be obtained. Another strategy consists in balancing the probability by the volume V_i of the block B_i :

$$p_{i|i \in [1, n]} = \frac{V_i}{\sum_{i=1}^n V_i} \quad (4)$$

The volume of a block defined by several implicit faults can be calculated using the method presented in [29].

Once a block $B_{selected}$ has been drawn, an isovalue f corresponding to the fault ($\mathcal{F}'(x, y, z) = f$) can be drawn in $B_{selected}$ in different manners. As for selecting a block, each location in the block can be equiprobable. Therefore the isovalue can be drawn from a uniform law whose extremities are the minimum and maximum values of the field $\mathcal{F}'(x, y, z)$ in the block $B_{selected}$. However, as observed in [21, 22], main sub-seismic faults tends to repulse each other. A simple way to simulate such a behavior is to draw the isovalue corresponding to the fault from a symmetric triangular or truncated Gaussian law so that medium positions in the block are privileged.

3.2.3. Order of simulation

In the general case, fault families are simulated in chronological order, the oldest one first. Consequently, all the faults belonging to the same family are branching faults for the faults belonging to older families (Fig. 7).

3.2.4. Case of cogenetic faulting

Faults with different structural characteristics (i.e., belonging to different families) may initiate simultaneously at the geological time scale and thus truncate each other. One example of such a situation are conjugate faults, corresponding to steeply opposed-dipping faults. In this case, fault families cannot be simulated one after the other. Instead, let be S_{coeval} the set of all the faults to be simulated belonging to cogenetic families. The method is iterative: a fault is drawn in the set S_{coeval} and added randomly in the binary tree, until S_{coeval} is empty. Consequently, faults belonging to a given family may be parent or child for the other cogenetic families, hence different truncation rules between families (Fig. 8d).

Figure 6: Non uniqueness of the representation of a fault array in a binary tree. *a.* 3D diagram representing three faults. The faults F_1 and F_2 are not in contact so they can either be parent or child in the binary tree. *b.* Representation of the three faults in a binary tree with F_1 as the parent fault. *c.* F_2 is now the root of the tree without any change about their truncation in the diagram. There may be a consequence of the change deeper, outside the diagram.

Fig. 6. Non unicité de la représentation d'un ensemble de failles dans un arbre binaire. *a.* Diagramme 3D représentant 3 failles. Les failles F_1 et F_2 ne sont pas en contact. Par conséquent, elles peuvent être père ou fils dans l'arbre binaire. *b.* Arbre binaire avec F_1 en tant que faille parente. *c.* F_2 est maintenant la racine de l'arbre mais aucun recoupement n'a changé. Il se peut que le recoupement change plus en profondeur, en dehors du diagramme.

3.2.5. Case of cross-cutting faults

A special situation may occur when a fault is offset by other faults (Fig. 5c). Indeed, in this case, the parent fault in the tree is the youngest one. This situation can be obtained by simulating the youngest fault F_{young} ($F_{young}(x, y, z) = f_{young}$) first and then simulating the shifted fault $F_{shifted}$ in a block (adding it at one leaf as usually). Then, depending on the displacement of the cutting fault F_{young} , $F_{shifted}$ may be added to

another leaf. Assuming no rotation of F_{young} 's displacement, $F_{shifted}$ is defined by the same scalar field but by different isovalues depending on the fault block:

- $F_{shifted}(x, y, z) = f_- | F_{young}(x, y, z) \leq f_{young}$
- $F_{shifted}(x, y, z) = f_+ | F_{young}(x, y, z) \geq f_{young}$

4. Perspectives and conclusion

We have introduced a new framework for modeling structural uncertainties. In particular, the method goes beyond the perturbation of deterministic 3D structural interpretations, but considers the uncertainty about connectivities between structural interfaces (Fig. 8). We expect this method to provide a basis for further advances in subsurface uncertainty management, including:

- Taking into account additional data, e.g. field and seismic data, size distribution, slip information. In the case seismic data is available, the global vertical displacement is known for the fault zone. The sum of the simulated displacement for all the faults present laterally in the zone must be equal to the displacement known from seismic data. Some work has also been done to underline the correlation between the displacement of a fault and its size [30, 31]. Such correlations could be used either to simulate the displacement or laterally dying and syndimentary faults, depending on the available data.
- How to model particular fault zones? Using our method, realistic fault arrays are obtained but not particular configurations. One may want to simulate, e.g. a fault relay zone, for there is evidence such a structure occurs in the studied area although uncertainties remain. For instance, the probability of a breaching fault to connect two segments of a relay zone must only be defined for the block in between the two segments. It means that some blocks cannot be selected during the simulation, i.e. the binary tree structure is constrained.
- Flower structures between two faults is another challenge since in this case, each fault is both parent and child of the other fault, corresponding to cycles in the tree. To solve this problem, the geometry of a flower structure may be obtained by considering one main fault depending on the sliding direction and an inactive lentil bounded to the sliding surface [32].

The method takes advantage of implicit modeling for both topology description and changes. Each fault is fully described by a monotonic volumetric function $\mathcal{F}'(x, y, z)$ corresponding to the sum of a reference field $\mathcal{F}(x, y, z)$, computed from statistical or hard data, and a spatially correlated random field $\mathcal{R}(x, y, z)$ corresponding to the associated uncertainties. We believe this implicit representation provides a convenient and robust way of guaranteeing the model consistency.

A binary tree has been introduced to describe the spatial relationships between faults. The tree should be considered as a descriptor of fault events, a fault being a branching fault for its ascending branch in the tree. During the fault simulation, faults

Figure 7: Steps for generating a fault network. *a.* Two faults belonging to the same family and the corresponding tree have been simulated. Two faults belonging to another fault family remain to simulate. *b.* One leaf of the tree is drawn depending on the random function used (e.g. uniform, balanced by block's volume). Once a block is drawn, the algorithm generates a field for the next fault and perturbs it using the method presented in Fig.3. Then, an isovalue is drawn among the range of values present in the selected block. *c.* The same process is repeated to add another fault.

Fig. 7. Étapes de la génération d'un réseau de failles. *a.* Deux failles appartenant à la même famille ainsi que l'arbre binaire correspondant ont déjà été simulés. Deux failles appartenant à une autre famille doivent encore être ajoutées. *b.* Un bloc est tiré selon une fonction aléatoire (ex., uniforme, proportionnelle au volume des blocs). Une fois le bloc sélectionné, un champ scalaire est simulé pour la prochaine faille en utilisant la méthode présentée en Fig.3. Une isovaleur est ensuite tirée parmi les valeurs présentes dans le bloc. *c.* Le même procédé est répété afin d'ajouter une faille supplémentaire.

are added in the tree according to their relative age in order to obtain a fault network honoring input structural constraints. Fault arrays with different topologies are obtained

Figure 8: Simulation results illustrating different levels of structural uncertainties in a vertical fault zone. *a – b*: low uncertainty, only the geometry of fault surfaces is uncertain, the connectivity is fixed. *c – d*: large uncertainty, both the geometry and the connectivity are uncertain. In *c*, the fault family oriented NS is the main family, the second fault family oriented WS is branching on the first family. In *d*, even the faulting events are uncertain, fault families are considered as cogenetic families.

Fig. 8. Résultats de simulation illustrant différents niveaux d'incertitude dans une zone de faille verticale. *a – b*: faible incertitude, seule la géométrie des failles est incertaine, la connectivité est fixe. *c – d*: incertitude importante, la géométrie ainsi que la connectivité des failles sont incertaines. Pour le cas *c*, la famille de faille orientée Est-Ouest est secondaire par rapport à la famille de faille orientée Nord-Sud. Pour le cas *d*, l'ordre chronologique des deux événements de fracturation est incertain, ce qui revient à considérer les deux familles de faille cogénétiques.

by simulating different binary trees.

Such a multi-realization approach enables to assess the inherent uncertainties to geological data sets. Existing methods are mostly used in the oil industry to reduce economical risks. However, we believe it has a strong potential in other application fields such as potential field interpretation or seismic waveform inversion.
